Abstract. The influence of seawater carbon dioxide (CO₂) concentration on the size distribution of suspended particles (2–60 µm) and on phytoplankton abundance was investigated during a mesocosm experiment at the large scale facility (LFS) in Bergen, Norway, in the frame of the Pelagic Ecosystem CO₂ Enrichment study (PeECE II). In nine outdoor enclosures the partial pressure of CO₂ in seawater was modified by an aeration system to simulate past (∼190 µatm CO₂), present (∼370 µatm CO₂) and future (∼700 µatm CO₂) CO₂ conditions in triplicates. Due to the initial addition of inorganic nutrients, phytoplankton blooms developed in all mesocosms and were monitored over a period of 19 days. Seawater samples were collected daily for analysing the abundance of suspended particles and phytoplankton with the Coulter Counter and with Flow Cytometry, respectively. During the bloom period, the abundance of small particles (<4 µm) significantly increased at past, and decreased at future CO₂ levels. At that time, a direct relationship between the total-surface-to-total-volume ratio of suspended particles and DIC concentration was determined for all mesocosms. Significant changes with respect to the CO₂ treatment were also observed in the phytoplankton community structure. While some populations such as diatoms seemed to be insensitive to the CO₂ treatment, others like Micromonas spp. increased with CO₂, or showed maximum abundance at present day CO₂ (i.e. Emiliania huxleyi). The strongest response to CO₂ was observed in the abundance of small autotrophic nano-plankton that strongly increased during the bloom in the past CO₂ mesocosms. Together, changes in particle size distribution and phytoplankton community indicate a complex interplay between the ability of the cells to physiologically respond to changes in CO₂ and size selection. Size of cells is of general importance for a variety of processes in marine systems such as diffusion-limited uptake of substrates, resource allocation, predator-prey interaction, and gravitational settling. The observed changes in particle size distribution are therefore discussed with respect to biogeochemical cycling and ecosystem functioning.

1 Introduction

The increase in atmospheric CO₂ concentration since the beginning of industrialisation, associated risks of ocean acidification, and the potential consequences for marine carbon cycling and global climate have recently gathered attention beyond purely scientific interest. Prior to the industrial burning of fossil fuels, CO₂ concentrations varied between 180 and 280 µatm, with the lower values observed during glacial times. Since the middle of the 18th century, the atmospheric concentration of CO₂ has increased rapidly from 280 µatm in 1998, and several future scenarios predict a further increase to 750 µatm in 2100 (IPCC scenario IS92a) (Houghton et al., 2001). The seawater carbonate chemistry has responded noticeably, with a decrease from preindustrial surface ocean pH of 8.25 down to 8.08 presently. Modelling studies predict a further reduction of pH by 0.7 up to the year 2300, which would be more than experienced by marine life for the last 300 000 years (Caldeira and Wickett, 2003).

Although CO₂ plays a fundamental role for organic matter production in the ocean, as it is a substrate in algal photosynthesis, the direct effects of changes in CO₂ availability on organism performance, and their possible transfer to the
ecosystem level are still poorly understood. Only recently, studies showed that marine autotrophic communities such as seagrasses (Zimmerman et al., 1997), macroalgae (Gao et al., 1993), diatoms (Riebesell et al., 1993; Chen and Durbin, 1994), coccolithophores (Riebesell et al., 2000; Delille et al., 2005; Engel et al., 2005), and cyanobacteria (Qiu and Gao, 2002, Barcelos e Ramos et al., 2007; Hutchins et al., 2007) exhibit higher rates of production under CO$_2$ enrichment. It has also been shown that phytoplankton assemblages can experience marked shifts in composition under elevated pCO$_2$ conditions (Boyd and Doney, 2002; Tortell et al., 2002).

The previous reluctance to investigate direct effects of CO$_2$ on marine ecosystems largely resulted from the assumption that CO$_2$ is a non-limiting substrate for primary production in seawater. Although CO$_2$ concentrations in seawater range only between 8 and 22 µmol L$^{-1}$ (Goerike and Fry, 1994), the total reservoir of dissolved inorganic carbon is about ~2000 µmol L$^{-1}$. Thus, CO$_2$ is continuously supplied from the pool of bicarbonate and carbonate. Riebesell et al. (1993) showed that marine phytoplankton may indeed be limited by ambient CO$_2$ availability and respond to increased CO$_2$ concentration with increased growth rates. These results were somewhat contradictory to theoretical considerations, which indicated that for most phytoplankton cells the supply with CO$_2$ by diffusion is much larger than the cell’s need for carbon (Wolf-Gladrow et al., 1999). Seemingly, it is the inefficiency of the CO$_2$/O$_2$ fixing enzyme Ribulose-1,5-bis-phosphate-carboxylase/oxygenase (RubisCo), with a half-saturation constant (K$_m$) of 20–70 µmol L$^{-1}$ (Badger et al., 1998), which causes a rate limitation of primary production in marine phytoplankton. However, measurements of primary production of various phytoplankton species revealed much lower K$_m$ values, indicating an enhanced CO$_2$ concentration at the site of carboxylation (Raven and Johnson, 1991; Rost et al., 2003; Giordano et al., 2005). Species with a low K$_m$ value have a high affinity to CO$_2$ and/or HCO$_3^-$ and nearly saturate primary production at present day values, while at the same time minimizing energy loss due to photorespiration. An increase of seawater CO$_2$ must be anticipated to have little effect on primary production in these species. In contrast, for species with high K$_m$, such as the coccolithophore *Emiliania huxleyi*, an enhancement of carboxylation can be expected, if CO$_2$ concentration increase from low values (6–8 µmol L$^{-1}$), as estimated for the last glacial maximum to high concentration as expected for the future ocean (~22 µmol L$^{-1}$) (Rost and Riebesell, 2004). Thus, under conditions where CO$_2$ concentration regulates growth (no co-limitation), species with high CO$_2$ affinity perform better and might out-compete those with lower affinity. The K$_m$ value for CO$_2$ depends, among others, on the capability of the phytoplankton cell to express carbon concentrating mechanisms (CCMs), which include active uptake of CO$_2$ and/or HCO$_3^-$ and/or enzymatically enhanced conversion of HCO$_3^-$ to CO$_2$ (Raven and Johnson, 1991; Giordano et al., 2005). CCM operation has been observed in many marine microalgae, and we can expect selective advantages for those species that most efficiently apply CCMs to enhance carbon acquisition and cell growth. However, like any enzymatically driven process, CCMs require energy and substrates, in particular nitrogen, phosphate (ATP) and micronutrients for the synthesis and activation of involved enzymes, such as carbonic anhydrase (Young and Beardall, 2005; Beardall et al., 2005). Thus, the ability to express CCMs under natural conditions may be restrained by nutrient and light availability.

On the community level, theoretical considerations show how phytoplankton respond to changes in substrate availability by variation of community size structure, even in the absence of grazing (Irwin et al., 2006). In general, small cells have a higher surface-to-volume ratio and can faster satisfy the demand for substrates that are transported towards the cell by diffusion. Accordingly, if we assume that diffusion is a significant process for CO$_2$-supply to the cell, we principally expect smaller cells to have a selective advantage over larger cells, when CO$_2$ is limiting. Hence, size spectra of natural phytoplankton communities may be affected by CO$_2$ diffusive transport processes (up-scaling effects).

To our knowledge, no study has addressed direct effects of CO$_2$ concentration on the size distribution of cells during phytoplankton blooms so far, or considered selective advantage of cell size variation versus physiological performance with respect to carbon uptake. Here, we investigate the effect of CO$_2$ availability on the size frequency distribution of particles under conditions mimicking a phytoplankton bloom during a mesocosm experiment.

2 Material and methods

2.1 Set-up of the mesocosm experiment

The study was conducted in the framework of the Pelagic Ecosystem CO$_2$ Enrichment Study (PeECE II) in spring 2003 at the Large Scale Facility in Bergen, Norway. Nine outdoor mesocosms (~20 m$^3$, 9.5 m depth) were filled with unfiltered, nutrient-poor, post-bloom Fjord water, which was pumped from 2 m depth adjacent to the raft and aerated with CO$_2$/air mixtures in order to achieve 3 different CO$_2$ levels (190 µatm, 370 µatm and 700 µatm) in triplicates. The general set-up of the mesocosm study has been described in Engel et al. (2005) and Delille et al. (2005) for a similar experiment (PeECE I). Alterations applied during PeECE II are described in Grossart et al. (2006) and are similar to those of PeECE III (Schulz et al., this volume). In order to separate the upper from the lower water column, freshwater was initially added to the surface of each mesocosm, resulting in a halocline at about 5 m depth. During the study, the upper 5 m were continuously mixed using aquarium water pumps. Temperature and salinity profiles were recorded daily using a
CTD. Nutrients were added initially to obtain concentrations in the seawater of 8.6 μmol L⁻¹ nitrate, 0.38 μmol L⁻¹ phosphate and 12 μmol L⁻¹ silicate (Carbonnel and Chou, personal communication). Daily samples were taken from each mesocosm with 4 m long Polyethylene tubes (10 cm diameter), integrating the upper water column and transferred to 20 L carboys. Immediately after sampling the carboys were brought to the lab and subsamples were taken for various analyses. Intrusion of higher salinity water was observed for mesocosm 9 at day 9. Therefore, data from this mesocosm after day 9 were disregarded.

2.2 Carbonate chemistry

Samples for total alkalinity (TA) and total dissolved inorganic carbon (DIC) were poisoned with HgCl₂ on collection, stored in bottles with ground glass stoppers and filtered through GF/F filters prior to analysis. TA was measured using the classical Gran potentiometric titration method (Gran, 1952). The reproducibility of measurements was usually within 4 μmol kg⁻¹. Dissolved inorganic carbon (DIC) was measured by coulometric titration (Johnson et al., 1987) with a precision of 2 μmol kg⁻¹. Other CO₂ system variables (pH, CO₃⁻, HCO₃⁻) were calculated using the CO₂SYS program (Lewis and Wallace, 1998).

The pCO₂ in seawater was measured by means of an equilibrator (Frankignoule et al., 2001) coupled to an infrared analyzer (Li-Cor 6262). The system was calibrated routinely with air standards with nominal mixing ratios of 0 and 375 atm of CO₂ (Air Liquide Belgium). Temperature at the inlet of the pump and in the equilibrator was measured simultaneously with two Li-Cor thermosensors. Temperature within the upper mixed 5m ranged between 7.9°C and 10.0°C during the study for all mesocosm. For each measurement of pCO₂, samples for TA were also taken. The pCO₂ was corrected for temperature changes using the dissociation constants of Roy et al. (1993) and TA measurement.

2.3 Particulate organic matter

Total particulate carbon (TPC) and particulate organic nitrogen (PON) were determined by elemental analysis from 1 L (day 0–12) or 0.5 L (day 13–19) samples filtered gently (200 mbar) through precombusted (24 h, 500°C) glass fibre filters (GF/F, Whatman). For determination of POC, filters were fumed for 2 h with saturated HCl to remove all particulate inorganic carbon, and dried for 2 h at 50°C. TPC, POC, and PON were subsequently measured on an Europa Scientific ANCA SL 20–20 mass spectrometer.

2.3.1 Solid particles

Concentration and size distribution of solid particles were determined with a Beckmann Coulter Counter (Coulter Multisizer III), according to Sheldon and Parsons (1978). Three replicate samples of 2000 μL volume were measured daily for each mesocosm using a 100 μm orifice tube. Particles between 2 and 60 μm equivalent spherical diameters (ESD) were binned into 256 size classes. On several days during the bloom, three replicates of 20 mL were counted with a 280 μm orifice to reveal potential abundance of larger particles. These measurements showed that abundance of particles beyond 60 μm ESD was negligible (<1 count/10 ml), and the data were therefore not included in this analysis.

2.3.2 Chlorophyll-a

Concentration of Chl-a was determined fluorometrically from 100 mL samples filtered onto duplicate 0.45 μm cellulose nitrate filters and extracted in 90% acetone overnight. Chl-a concentration was measured using a Turner Design fluorometer (model 10-AU) and a standard solution of pure Chl-a for calibration.

2.3.3 Flow Cytometry

Phytoplankton counts were performed with a FACSCalibur flow-cytometer (Becton Dickinson) equipped with an air-cooled laser providing 15 mW at 488 nm and with a standard filter set-up. The cells were analysed from fresh prefiltered (30 μm mesh) samples at high flow rate (~60 μl min⁻¹). Autotrophic groups were discriminated on the basis of their forward light scatter (FLS) and right angle light scatter (RALS) and chlorophyll fluorescence. Counts were assigned to phytoplankton species based on the species signature as obtained from monoclonal cultures and cross-checked by microscopy. Classification of “Micromonas-like” cells was adopted from Larsen et al. (1999). Species Listmode files were analysed using WinMDI.

2.4 Statistical treatment of data

Average values are given by the statistical mean (x̄) and its standard deviation (SD). Mean values were compared by means of a t-test. Significance of the correlation coefficient (r²) against H₀: r=0, was tested by a Student-test according to Sachs (1974):

\[ t = \frac{r \sqrt{n-2}}{\sqrt{1-r^2}} \]  

with n=numbers of observations and the degree of freedom, df=n-2. H₀ (r²=0) is rejected for t≥t₀ₙ₋₂; p. The influence of the CO₂-treatment on biological or chemical variables was determined by means of the analysis of variance (ANOVA) or covariance (ANCOVA). The effect of the CO₂-treatment on a linear relationship between two biological or chemical variables was tested by comparing the slopes (b) of the linear regressions (F(x)=b(x)+a), as calculated for each treatment separately, with a t-test (Sachs, 1974) with dF=n₁+n₂–4. Significance level of each test was p<0.05.
3 Results

3.1 Bloom development

Following the development of the phytoplankton bloom, Chl-α increased exponentially in each of the mesocosms until a maximum value was reached between day 9 and day 13 of the experiment (Fig. 1a). The peak of the Chl-α concentration coincided with the depletion of nutrients, which was observed for nitrate between day 11 and 12 for all mesocosms (Carbonnel and Chou, personal communication). Thereafter, Chl-α concentration declined until the end of the experiment. The bloom can be divided into a pre-bloom phase that covered the first week of the experiment, a bloom phase during the second week, and a post-bloom phase towards the end of the experiment. Inevitable variations during the initialisation procedure introduced small variability among all mesocosms. Therefore, we find deviations regarding the timing of the maximum Chl-α concentration and the onset of decline phase within the CO₂ treatments (one to three days). For later reference we defined more narrow windows for the three phases of the experiment that can clearly be differentiated in all mesocosms: the pre-bloom: days 1–3, the bloom peak: Chl-α max ±1 day, and the post bloom: days 18–20.

With respect to the CO₂-treatment no significant difference in Chl-α concentration or in the timing of the maximum concentration were observed. Nutrient draw-down was not significantly different among the CO₂ treatments at any time of the experiments (Carbonnel and Chou, personal communication) either.

Particulate organic carbon (POC) concentration started with $17\pm3.5 \mu mol L^{-1}$ and increased throughout the study in all mesocosms to final values of $42-49 \mu mol L^{-1}$ (Fig. 1b). POC concentration was not related to CO₂ concentration (ANOVA). Particulate organic nitrogen (PON) concentration was initially $2.4\pm0.5 \mu mol L^{-1}$ and increased to maximum values of $7.1\pm1 \mu mol L^{-1}$ on day 9 of the bloom (Fig. 1c). PON concentration was remarkably similar in all mesocosms and no significant effects of the CO₂ treatment on PON concentration was determined (ANOVA).

Maximum molar [POC]:[PON] ratios were observed during the post-bloom phase with $8.6\pm0.8, 10\pm1.0$ and $9.7\pm1.3$ for the past, present and future CO₂ treatment, respectively. No significant CO₂ effect on the carbon-to-nitrogen (C:N) ratios of POM was determined (ANOVA).

3.2 Particle abundance and size distribution

More than 95% of all particles between 2 and 60 µm equivalent spherical diameter (ESD) were detected with the Coulter Counter in the size range between 2 and 10 µm ESD. Larger particles were counted randomly, with abundances that fall into the range of uncertainty (variability) of one treatment, represented by three mesocosms (replicates). Total abundance of Coulter Counter particles (CCP) measured
shortly after initialisation in all mesocosms, was indifferent among treatments, yielding an average of 7750 ± 560 counts mL⁻¹. The CCP abundance increased exponentially during the bloom until maximum concentrations were reached between day 11 and day 15 (day 9 for M9) (Fig. 2). Maximum CCP abundances, as averaged separately for the three CO₂ treatments, were 43 000 ± 5000 counts mL⁻¹ for the past, and 52 600 ± 9500, and 42 500 ± 11600 counts mL⁻¹ for the present and future CO₂ treatment, respectively. The net specific growth rate (µᵣ) for CCP during the phase of exponential growth was calculated for each mesocosm: 

\[ µᵣ = \frac{\ln(C_i) - \ln(C_{i-1})}{t_i - t_{i-1}} \],

with \( \ln(C_i) \) and \( \ln(C_{i-1}) \) being the natural logarithm of CCP concentrations at two consecutive days. Maximum values for \( µᵣ \) ranged between 0.30 d⁻¹ (M1) and 0.68 d⁻¹ (M7). No significant effects of the CO₂ treatment on the parameter (µᵣ) or on the maximum values for µᵣ were identified.

The size frequency distributions, or size spectra, of CCP, changed over time in all mesocosms (Fig. 3). Size spectra were not significantly different for the three treatments during the pre-bloom phase (ANOVA), but developed differently during growth of the phytoplankton community. Given the present day CO₂ treatment as a reference, we find two distinct maxima in the size spectra, one around 2 µm ESD and another close to 5 µm ESD. Compared to the present day CO₂ treatment, there was a lack of the larger population in the past CO₂ treatment, whereas a drastic reduction of particles abundance was observed at small size (<4 µm) in the future CO₂ treatment (Fig. 3). These distinct differences persisted during the post-bloom phase, but with an increase in variability within the individual treatments.

Differences in size distribution were reflected in significant differences of the median particle size of CCP among the CO₂ treatments over the course of the experiment (ANOVA, \( p < 0.001 \), \( t\)-test future−present \( p < 0.005 \), \( t\)-test present−past \( p < 0.001 \); Fig. 4). The highest value for median particle size of CCP was observed on day 7 in the future CO₂ treatment with 4.23 ± 0.11 µm ESD (mean ± 1 SD calculated from three mesocosms). The maximum value for median size in the present day CO₂ treatment was observed at day 7 also, but with a slightly smaller value of 4.12 ± 0.10 µm ESD. Clearly smaller particles were observed in the mesocosms of the past CO₂ treatment, yielding a maximum median size of 3.70 ± 0.05 µm ESD at day 5. The temporal development of the median size of particles followed similar dynamics irrespectively of the CO₂ concentration; i.e. the median size increased at the beginning of the experiment, had a maximum value during mid or late pre-bloom, a declining phase during the peak of the bloom, and varied only little during the post-bloom phase.

However, median sizes in past CO₂ treatment deviated from the present day or future CO₂ already on day 4. Moreover, the maximum value of median sizes was observed on day 5 in past CO₂ treatment and thus two days earlier than in the other two treatments. This indicates that the absolute abundances, as averaged separately for the three CO₂ treatments, were 43 000 ± 5000 counts mL⁻¹ for the past, and 52 600 ± 9500, and 42 500 ± 11600 counts mL⁻¹ for the present and future CO₂ treatment, respectively. The net specific growth rate (µᵣ) for CCP during the phase of exponential growth was calculated for each mesocosm: 

\[ µᵣ = \frac{\ln(C_i) - \ln(C_{i-1})}{t_i - t_{i-1}} \],

with \( \ln(C_i) \) and \( \ln(C_{i-1}) \) being the natural logarithm of CCP concentrations at two consecutive days. Maximum values for \( µᵣ \) ranged between 0.30 d⁻¹ (M1) and 0.68 d⁻¹ (M7). No significant effects of the CO₂ treatment on the parameter (µᵣ) or on the maximum values for µᵣ were identified.

The size frequency distributions, or size spectra, of CCP, changed over time in all mesocosms (Fig. 3). Size spectra were not significantly different for the three treatments during the pre-bloom phase (ANOVA), but developed differently during growth of the phytoplankton community. Given the present day CO₂ treatment as a reference, we find two distinct maxima in the size spectra, one around 2 µm ESD and another close to 5 µm ESD. Compared to the present day CO₂ treatment, there was a lack of the larger population in the past CO₂ treatment, whereas a drastic reduction of particles abundance was observed at small size (<4 µm) in the future CO₂ treatment (Fig. 3). These distinct differences persisted during the post-bloom phase, but with an increase in variability within the individual treatments.

Differences in size distribution were reflected in significant differences of the median particle size of CCP among the CO₂ treatments over the course of the experiment (ANOVA, \( p < 0.001 \), \( t\)-test future−present \( p < 0.005 \), \( t\)-test present−past \( p < 0.001 \); Fig. 4). The highest value for median particle size of CCP was observed on day 7 in the future CO₂ treatment with 4.23 ± 0.11 µm ESD (mean ± 1 SD calculated from three mesocosms). The maximum value for median size in the present day CO₂ treatment was observed at day 7 also, but with a slightly smaller value of 4.12 ± 0.10 µm ESD. Clearly smaller particles were observed in the mesocosms of the past CO₂ treatment, yielding a maximum median size of 3.70 ± 0.05 µm ESD at day 5. The temporal development of the median size of particles followed similar dynamics irrespectively of the CO₂ concentration; i.e. the median size increased at the beginning of the experiment, had a maximum value during mid or late pre-bloom, a declining phase during the peak of the bloom, and varied only little during the post-bloom phase.

However, median sizes in past CO₂ treatment deviated from the present day or future CO₂ already on day 4. Moreover, the maximum value of median sizes was observed on day 5 in past CO₂ treatment and thus two days earlier than in the other two treatments. This indicates that the absolute
value of median size as well as the timing of the saddle point was affected by the CO$_2$-treatment.

Effects of the CO$_2$ treatment on particles size were also reflected in the ratio of the total surface to total volume (TS:TV), calculated as

$$\frac{\text{TS : TV}}{\Sigma_{i}^{\text{ESD}_i} \left\{ \pi (\text{ESD}_i)^2 \times n_i \right\}} / \Sigma_{i}^{\text{ESD}_i} \left\{ 1/6 \pi (\text{ESD}_i)^3 \times n_i \right\}$$

(2)

with ESD$_i$ being the smallest (2 $\mu$m) and ESD$_{ii}$ the largest (60 $\mu$m) size class observed.

During the 7-day period of the bloom of the phytoplankton community, TS:TV ratios were significantly related to DIC concentration of seawater ($p<0.001$) and decreased with increasing DIC (Fig. 5).

3.3 Phytoplankton community composition

Total number (N) of autotrophic cells, as determined by Flow Cytometry in the size range 1.5–30 $\mu$m, was 6300$\pm$1700 N mL$^{-1}$ initially and increased throughout the experiment in all mesocosms (Fig. 3a–c). Maximum average phytoplankton abundance was 36000$\pm$1500 N mL$^{-1}$, 38500$\pm$9450 N mL$^{-1}$ and 34500$\pm$3930 N mL$^{-1}$ for the past, present day and future CO$_2$ treatment, respectively. During the course of the experiment, total abundance of phytoplankton cells differed significantly among the treatments (ANOVA, $p<0.005$), with the future CO$_2$ treatment having the lowest autotrophic cell abundance ($t$-test, $p<0.001$). Comparing the total abundance of phytoplankton (within size range 1.5–30 $\mu$m) with total CCP abundance in the size range 2–60 $\mu$m ESD revealed a similar temporal development (Fig. 3a–c). However, the Flow Cytometry data showed systematically higher total phytoplankton abundance during the pre-bloom and bloom...
phase up to day 10 of the experiment. This can be attributed to the lower size detection limit of the Flow Cytometer. After day 10, the number of CCP increased over the number of phytoplankton, indicating the transition from a small-celled autotrophic community to a mixed community, including heterotrophic organisms and detritus particles. In general, the relative contribution of autotrophic cells to total particles was highest in the past CO$_2$ treatment and similar in the present day and the future CO$_2$ treatment.

The species composition of phytoplankton, as determined by Flow Cytometry, indicate that the phytoplankton community was initially similar in all enclosures and was dominated, in terms of numbers, by cells with a signature similar that of the phytoflagellate *Micromonas* spp.; termed *Micromonas*-like in the following (Fig. 6). Other major phytoplankton species included diatoms, specifically *Nitzschia* spp., the cocolithophore *Emiliania huxleyi*, and the nanoflagellate *Phaeocystis* spp.. During the bloom, the relative abundance of phytoplankton species developed significantly differently in the CO$_2$ treatments (ANOVA, $p<0.05$). In the past CO$_2$ treatment, populations of small ($<4 \mu m$) unidentified autotrophic cells grew rapidly and dominated the community structure during the bloom to a large extend. The *E. huxleyi* population was most prominent in the present, and, although to a smaller degree, in the future CO$_2$ treatment. The *E. huxleyi* population was determined by the Coulter Counter in the size range $4-8 \mu m$ ESD and identified in the future and present day mesocosms by clear peaks. Because no significant differences between the future and present day CO$_2$ treatment were observed for the median particle size in this $4-8 \mu m$ ESD size window, we can assume that the size of the *E. huxleyi* population itself did not vary significantly with CO$_2$. Diatoms ($>4 \mu m$) contributed between 4 to 12% to total phytoplankton abundance with the higher values observed during the pre-bloom phase. Within the group of diatoms, a smaller size population of *Nitzschia* was differentiated from a group of larger ($>8 \mu m$) diatoms. For both diatom groups, no significant differences in terms of absolute and relative abundance among the CO$_2$ treatments were observed (ANOVA, $p>0.05$). During the post-bloom phase the average phytoplankton composition of the future and present CO$_2$ treatment approached those observed for the past treatment during the bloom and no significant CO$_2$ related differences were determined.

### 4 Discussion

The aim of this study was to test the hypothesis that CO$_2$ concentration can affect the size distribution of cells during the course of a phytoplankton bloom. Our results revealed that the size distribution of suspended particles in the range $2-60 \mu m$ ESD differed significantly among the three CO$_2$ treatments during the bloom phase itself, when biological processes were dominated by autotrophic growth. There were several indications for particles tending to be smaller at lower CO$_2$ concentration and larger at higher CO$_2$ concentration relative to the present day concentration, expressed by the median size of suspended particles, by the total-surface-to-total-volume ratio, and by the multi-modal distribution of particle size. Changes in CO$_2$ also led to significant structural effects on the autotrophic community, as indicated by the different abundance of phytoplankton taxa using Flow Cytometry. Thereby, the major phytoplankton populations were affected differently. While some populations such as diatoms seemed to be insensitive to the CO$_2$ treatment, others
increased in abundance with CO₂, or were most abundant at present day CO₂.

4.1 CO₂ effects on size distribution of suspended particles

Causes for changes in the size distribution of autotrophic cells can be manifold. In general, metabolic processes, such as growth, nutrient and light acquisition, or respiration, are related to organism size (Peters, 1983). Grazers often select their prey according to size, and the settling rate of most types of marine particles increases with size. For marine phytoplankton, metabolic scaling has previously been shown for some processes such as nutrient uptake, photosynthesis and growth (Finkel et al., 2004). For others, such as respiration, the existence of size dependence has been questioned (Falkowski and Owens, 1978). Moreover, the relative surface area can be of greater importance than cell diameter, mass or volume with respect to processes such as nutrient uptake, because it is the surface that interferes with the outer medium containing the substrate reservoir. The relative surface area of a phytoplankton cell increases with decreasing size, but also with increasing eccentricity of the cells. Small or elongated phytoplankton species should be better competitors for resources, in particular when these limit biomass production (Grover, 1989). Therefore, small-sized phytoplankton cells are likely to dominate under oligotrophic conditions, whereas elevated nutrient concentration induce growth of larger cells (Irwin et al., 2006).

During this study, significant effects of the CO₂ treatment on particle size distribution were most obvious during the time of the bloom when autotrophic cells dominated particle abundance. This indicates a bottom-up effect of CO₂ on size on the phytoplankton community level. Particle size during this study, however, was derived from volume and expressed as equivalent spherical size without any additional information on the shape of the cells. Information gained from the Flow-Cytometer and from microscopy nevertheless revealed that most species in the size range 1.5–30 µm were indeed rather spherical, with the exception of Nitzschia spp.. Although the distal length of Nitzschia spp. is relatively large, their proximal size is small and thus the volume is small. However, abundance of Nitzschia spp. was not significantly different among the CO₂ treatments. Hence, eccentricity of cells did not bias the observation of a general increase in cell size with increasing CO₂ during this study.

During the bloom phase, the observed differences in particle size spectra and median particle size were related to differences in phytoplankton community composition. Micromonas-like cells and E. huxleyi, for example were more abundant in the present day and future than in the past CO₂ treatment. In the latter, smaller autotrophic nanoplanクトon clearly dominated the bloom by number. Size variations within individual species were presumably not related to the CO₂-treatment. However, at least for E. huxleyi potential changes in the proplast size may have been masked by
simultaneous changes in coccospere size due to potential effect of CO$_2$ on calcification (Riebesell et al., 2000). During a similar mesocosm study (PeECE I), when the phytoplankton community was clearly dominated by *E. huxleyi*, Engle et al. (2005) observed that the sizes and weights of coccospores were largest at low CO$_2$. During PeECE I, no significant differences in the phytoplankton community were observed with respect to the CO$_2$ treatment. One reason for the different outcome of PeECE I and II with respect to CO$_2$ influence on phytoplankton community composition may be that nutrients in the PeECE I-experiment were added in a NO$_3$ : PO$_4$ ratio of 30 and without any additional supply of silicate in order to favour the blooming of *E. huxleyi*. In the present study N : P : Si were added in “Redfield-ratio” in order to allow for a mixed assemblage of diatoms, coccolithophores and other autotrophic species.

### 4.2 CO$_2$ effects on phytoplankton community composition

Recent investigations on CO$_2$ acquisition in marine phytoplankton species demonstrated that many phytoplankton groups including diatom species such as *Skeletonema costatum* efficiently apply carbon concentrating mechanisms (CCMs) (Rost et al., 2003). CCMs can be understood as a physiological regulation of CO$_2$ acquisition to maintain high photosynthetic rates even at reduced CO$_2$ concentration. Goldman (1999) observed no reduction in cell growth of large diatom species until CO$_2$ concentrations fell as low as 4 µmol L$^{-1}$, indicating that growth of these species was not depending on the diffusional supply of CO$_2$, but was supported by CCMs. During this study the abundance of diatoms was not significantly different among the CO$_2$ treatments, supporting the idea that diatoms do not suffer from changes in CO$_2$ concentrations over a relatively wide range. Abundance of *E. huxleyi*, in contrast, was significantly reduced in the past CO$_2$ treatment. This is in accordance with our expectations, since *E. huxleyi* has been shown to have a low affinity to CO$_2$ (Rost et al., 2003). Abundance of *Micromonas*-like cells increased with increasing CO$_2$, indicating that this species does not apply CCMs efficiently, either. However, the strongest response to CO$_2$ concentration was observed in the group of small autotrophs that grew abundantly in the past CO$_2$ treatment, but little in the future CO$_2$ treatment. Changes in the abundance of these small cells were mainly responsible for the changes in size spectra compared to the present day treatment.

Interestingly, it was the group of small-celled algae that numerically dominated phytoplankton community at low CO$_2$, and not larger diatoms, which we expected to be good competitors based on their high CO$_2$ affinity and physiological capability. Microscopic observations revealed that the group of small cells comprised various phytoplankton taxa (Martin-Jezquel, personal communication), indicating that size itself was selected in the low CO$_2$ treatment. Because we did not determine CCM operations in phytoplankton during this study, we can only speculate about possible explanations for the observed CO$_2$-effects on phytoplankton abundance and size distribution. First, CCMs in diatoms, or other species, may have been co-limited by phosphate or light availability (Young and Beardall, 2005, Beardall et al., 2005) and were not efficient enough to give a competitive advantage at low CO$_2$ concentration. Phosphate concentrations during this study decreased strongly within the first week, while at the same time NO$_3$ : PO$_4$ ratios increased up to 28 (Carbonnel and Chou, personal communication), indicating high phosphorus demand of phyto- and bacterioplankton cells. To prevent depletion, PO$_4^{3-}$ was added again to all mesocosms on day 8. By this time differences in the particle size spectra had already evolved (Fig. 4). Thus, we cannot exclude that P limitation may have affected CCMs of algal species and was co-limiting active C- uptake in the past CO$_2$ mesocosms. If P were the potentially limiting nutritious element, we would expect that species allocating PO$_4^{3-}$ efficiently for reproduction have an advantage over those species, which additionally need to allocate PO$_4^{3-}$ for CCM operation. Under these circumstances, reduction of cell size would be beneficial to circumvent both P- and CO$_2$ limitation and may help to explain the observed relationship between size and DIC availability during this study. We may then speculate that future effects of elevated CO$_2$ concentration on the size spectrum of phytoplankton communities may especially occur in oceanic regions, where P is limiting phytoplankton production.

Another hypothesis would be that CCMs only acted as a surplus to carbon acquisition and were expressed equally well in all phytoplankton species observed in the past CO$_2$ treatment. Cassar et al. (2004) estimated that 50% of carbon uptake in a natural diatom population was comprised by HCO$_3^-$ uptake, the remaining 50% by CO$_2$. Reduction of cell size may therefore be pivotal to enhance the fraction of CO$_2$ taken up by diffusion, and to accelerate growth rates of small cells. Certainly, more investigations are needed to elucidate the interplay between size and physiological regulation of carbon uptake during natural phytoplankton blooms, and the impact on carbon acquisition and species selection in the future ocean.

During the post-bloom phase, species composition was quite similar in all CO$_2$ treatments, indicating that factors other than CO$_2$ were influencing species distribution at this time.

### 4.3 Potential consequences for carbon cycling

Particle size distribution and phytoplankton species composition were rather similar in the present day and future CO$_2$ treatment, and clearly different from the past CO$_2$ treatment. This is in accordance with the non-linear relationship between CO$_2$ concentration and primary production, indicating that the selective pressure towards a larger relative surface area, i.e. cell size reduction, for species relying on CO$_2$...
uptake, whatsoever, increase with decreasing CO₂ concentration. As mentioned above, we do not have information about potential enhancement of carbon uptake due to CCM operations in phytoplankton during this study. In order to estimate potential differences in carbon acquisition within the three CO₂ treatments due to the observed differences in cell size, we can only estimate the treatment effect on the diffusive supply with CO₂. To estimate the spectral distribution of CO₂ supply during the bloom phase in the three CO₂ treatments, we calculated theoretical rates of CO₂ supply to the cell according to the simplified model of Riebesell et al. (1993) (Fig. 7); see also Gavis and Ferguson (1975) and Wolf-Gladrow and Riebesell (1997) for further information. In alteration to Riebesell et al. (1993) CO₂-supply rates were calculated for each of the 256 size classes ranging from 2 μm ESD to 60 μm ESD using the average observed CO₂ concentrations during the ‘bloom-period’, i.e. 22.34, 14.28 and 8.49 μmol kg⁻¹ for the future, present day and past CO₂ treatment, respectively. A conversion factor (ak) of 400 was assumed, accounting for the HCO₃⁻–CO₂ equilibrium at the observed pH- and temperature range. The half-saturation constant (Km) was fixed to 10 μmol kg⁻¹, assuming that this is a representative value for a mixed phytoplankton community of diatoms, cocolithophores and Phaeocystis spp. However, varying Km from 0.5 to 20 had only little effect on the estimates for CO₂ fluxes (<0.1%) in our model. To calculate the maximum CO₂-supply rate (Vₘₐₓ=μₘₐₓ×Qₑ) for each size class, the maximum growth rate of cells (μₘₐₓ, d⁻¹) was calculated with a parameterization that scales with cell volume (V, μm³); μₘₐₓ=a(V)ᵇ; with a=5.37, b=-0.25 after Irwin et al. (2006); the carbon cell quota (Qₑ; pg C) was calculated using Qₑ=d(V)ᵉ, with d=0.436, e=0.863 after Verity et al. (1993). The results of these calculations show that the spectral distributions of total diffusive CO₂-supply during the time of the bloom were different in the three CO₂ treatments (Fig. 8). With the exception of the very low size range (<4 μm ESD), the estimated total CO₂-supply was higher at all size classes in the present day and future CO₂ treatment than in the past. Only at particle sizes <4 μm ESD, the higher abundance of particles in the past CO₂ treatment could partially compensate for the lower supply rates per cell. Integration over the size range 2–60 μm ESD yielded similar values for potential CO₂-supply for the future and present day CO₂ treatment with 100 μmol h⁻¹ kg⁻¹ and a much lower value for the past CO₂ treatment with 46 μmol h⁻¹ kg⁻¹. It has to be emphasized that these rates address only the aspect of diffusive flux of CO₂ to the cells. Averaged rates of primary production during this experiment yielded much lower values (Egge et al., 2007). Nevertheless, our calculations indicate that the total supply of cells with CO₂ was lowest in the past treatment despite the strong increase in the abundance of small cells, whereas the present day and future CO₂ treatment may have been equally productive despite the lower abundance of particles and autotrophic cells in the latter. A potentially higher CO₂-supply of cells in the future and present day CO₂ treatment is in accordance with earlier observations obtained during PeECE I, showing that the ΔDIC:Δ cell ratio increased with CO₂ concentration (Engel et al., 2005).

It is interesting to note that neither the potential differences in CO₂ supply nor the structural differences in the size spectra and in the phytoplankton community composition were reflected in the standing stocks of POC and PON. One might argue that PON production was rather related to the supply of inorganic nitrogen than to the availability of carbon, as inorganic nitrogen became exhausted in all mesocosms during the bloom development. As a consequence of the relative higher abundance of smaller particles, total particle volume
was lower in the past CO$_2$ treatment. The observation that PON concentration in the past treatment was not significantly different from those in the present-day and future treatment allows for two interpretations: either smaller particles contributed to PON in a higher proportion, or other particulate material that was not detected with the Coulter Counter, out of the size range 2–60 µm ESD, such as bacteria, contributed to PON to a higher degree. In fact, Verity et al. (1993) showed that the scaling exponent for the increase of nitrogen and carbon with cell volume is less than 1, and thus the volume of cells increases faster with size than the concentration of elemental components. Moreover, the scaling exponent for nitrogen is lower than for carbon leading to an increase of C:N ratios with cell size. However, estimates for the carbon and nitrogen content of cells vary even for cultures of the same species (Montagnes et al., 1994) and may not be representative for particles encountered during this study.

4.4 Potential consequence for ecosystem functioning

Structural changes in the size distribution of particles were observed during this mesocosm experiment, together with changes in the composition of the phytoplankton community. This response to changes in CO$_2$ cannot be explained with a unique scaling law (Enquist et al., 1998; Belgrano and Brown, 2002). Rather the differences observed are expected to include responses to micro-zooplankton grazing as well. Therefore, our results suggest a complex, yet unresolved, interplay of various size-dependent effects due to CO$_2$ supply, nutrient uptake and grazing. In general, nano- and small nanoplankton cells with a large surface-to-volume ratio are efficient in taking up resources, of which only a small fraction is needed for enzymes involved in C-fixation. These cells have a potential advantage under low substrate, and low CO$_2$ conditions but are susceptible to grazing by small protzoans and other micro-zooplankton. Larger phytoplankton cells have a smaller surface-to-volume ratio and are less competitive in terms of resource uptake, but they can allocate more luxury resources that may allow them to better compensate environmental changes (e.g. better acclimation to varying environmental factors such as CO$_2$). Their larger size can moreover be advantageous to escape micro-zooplankton grazing. Intermediate-sized cells have to find a balance between resources needed purely for growth, those that enhance physiological acclimation, and those resources that support predation defence. Thus, intermediate-sized nanoplatonk have no obvious advantage when it comes to escape grazing pressure, but also with respect to resource uptake. Instead, they rely on a fine balance (trade-off).

Exceptions may be given for species growing in chains, colonies or filaments, such as Phaeocystis and diazotrophic cyanobacteria. Overall, CO$_2$ induced changes in carbon utilization within the phytoplankton community are likely transferred to higher trophic levels, but may also change the quality of DOM. During this experiment, CO$_2$-sensitivity was found within a size spectrum that is rather narrow compared to the total phytoplankton size range (i.e. 1–5×10$^3$ µm) that can be observed in the ocean. The sensitive size range overlaps with those inherent to the microbial food web of pico- and nanoplankton. The microbial food web comprises a tight linkage between trophic interactions and DOM utilisation (Azam et al., 1983). Therefore, CO$_2$ related changes in the size distribution of phytoplankton involved in the microbial food web must be expected to affect DOM quality in conjunction with a response in micro-zooplankton grazing.
